INTRODUCTION

Lead is a widespread natural element in the environment. It is considered as one of the main persistent and common environmental pollutants (Joworaski, 1968). Lead is used in production of various manufactured products such as paints, printing, gasoline, batteries, water pipes, cosmetic products, pottery glazing, tank linings, brass faucets, toys, and many others (Harbison, 1998). Due to its toxic cumulative action in the environment, lead can affect all biological system via exposure from different sources including air, water, and food. Lead can translocate through the food chain and cause harmful effects to human and other living organisms. It is one of the poisonous metals in the environment and has deleterious impact to most organs of the human body (Duruihe et al., 2007). Lead enters into the body through three main routes including digestive and respiratory tracts, and skin. When it is absorbed into the blood, some of it is bound to erythrocytes and the remaining stay in plasma to be distributed to other tissues (Howard et al., 1973).

There are many evidences which report that lead is a poisonous factor which targets numerous organs such as kidneys, liver, nervous system, immune system, and haematopoietic system. Lead toxicity is associated with a number of physiological, morphological, and biochemical alterations such as liver dysfunction (Atsdr, 1993; Elayat and Bakheetf, 2010), haematological disorders (Mugahi et al., 2007), impairment of renal system functions (Suradkar et al., 2009), glucose metabolism abnormality (Ahrens, 1993; Yokoyama et al., 2000), and nervous system disturbances (Pitot, 1996).

Accumulation of lead in the body could lead to destructive impacts in haematic, gastrointestinal, and renal system (Correia et al., 2000). Lead toxicity has been associated with multiple forms of cancer, cardiovascular disorders, nephrotoxicity, and distraction of nervous system. Lead poisoning is related to sex, age, exposure duration, exposure route, absorption rate, frequency of intake, solubility, and retention percentage (Pitot, 1996). Exposure to excessive amount of lead has been shown to elevate blood pressure and cardiovascular disorders in adults, and to decrease the cognitive development and intellectual performance in children (CEC, 2002).

Exposure to lead has been shown to increase production of reactive oxygen species (ROS) and consequently induce lipid peroxidation and alteration of antioxidant defense systems in mice (Demirezen and Kadiriye, 2006) resulting in oxidative stress (Xenia et al., 2000). ROS are the by products of numerous degenerative reactions in various tissues, which affect the regular metabolism by damaging the cellular components (Foyer and Noctor, 2002). Decreasing the
possibility of lead interacting with critical bio-molecules and stimulating oxidative damage, or bolstering the cell's antioxidant defense might be attributed to beneficial role of antioxidant nutrients through exogenous supplementation of antioxidant molecules (Marija et al., 2004). Binding of lead to phosphatidylcholine in the cell membrane of red blood cells, lead to reduction of phospholipid levels. Lipid peroxidation has also been determined in tissue from different parts of the brain of lead-intoxicated rats. Lead exposure may cause hypochromic and normochromic anemia which results from reactive oxygen species production and subsequent erythrocyte hemolysis (Patrick, 2006). Therefore, the present study was designed to investigate the risk which may result from exposure to different doses of lead acetate on body weight, haematological indices, and the function of liver and kidney.

**MATERIALS AND METHODS**

**Experimental animals**

The study was conducted on forty male and forty female white wool albino mice, *Mus musculus*, aged three month. The animals were kept in standard compartmmented rectangular and well-ventilated cages. They maintained on standard healthy laboratory conditions at temperature of 18-24°C and twelve hours light and darkness. Animals were adapted to the new environment for fourteen days prior to study start. All mice had free access to drinking water and food, *ad libitum*, during the experimental period. They were fed with standard pellet diet (LabDiet, Missouri, USA) consisting of 60% starch, 20% casein, 10% cotton seed oil, 4% salt mixture, 5% cellulose, and 1% vitamin mixture.

**Lead dosage**

The animals were divided into four equal groups. Each group comprised of ten male and ten female separately and was marked as group I, II, III, and IV. The first group represented the healthy control animals, while the second, third and fourth groups were given 0.4, 0.8, and 1.2 mg/kg body weight of sub-lethal doses of lead acetate (Sigma-Aldrich Ltd., UK) respectively in their daily supply of drinking water for twelve weeks. Each mouse was weighed every week and its daily water intake was determined.

**Blood collection and analysis**

For haematological and biochemical investigations, blood was collected from each mouse individually. The animals were fasted for twelve hours prior to blood collection. All animals were anesthetized by chloroform and blood samples were collected immediately from their heart using heart puncture technique with the aid of disposable sterile syringe and needle (Sigma). Blood sample of each mouse was then transferred to a sterile capped tube containing anticoagulant EDTA (Greiner Bio-One, Frickenhausen, Germany) for haematological estimation. Some of blood was transferred to other sterile anticoagulant-free tube and centrifuged at 3000 rpm for about 10 min using centrifuge 5418 R (Eppendorf, Ontario, Canada) to obtain the serum for biochemical examination.

Blood cell counter URIT-2900 automated hematology analyser (Dhanawatari medical systems, DMS, India) was used to determine haematological indices including total erythrocyte count (TEC), total leucocyte count (TLC), Packed cell volume (PCV), Haemoglobin (Hb) concentration, mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC), and the amount of platelets.

Serum biochemical parameters were analysed using auto serum analyser, Selectra ProS (Merck Ltd., Germany) and Ecoline kits (Merck Ltd.) in accordance to manufacturer’s instructions. These parameters included aspartate aminotransferase (AST) or glutamic oxaloacetic transaminase (GOT), alanine aminotransferase (ALT) or glutamic-pyruvic transaminase (GPT), bilirubin concentration, gamma glutamyl transferase (GGT), lactate dehydrogenase (LDH), alkaline phosphatase (AKP), the concentration of blood urea nitrogen (BUN), and serum creatinine concentration.

**Statistical analysis**

The data provided in this study were analysed using statistical based methods, analysis of variance and student’s t-test to compare the difference between parameters. Results were expressed as mean values ± standard error. All statements of significance were based on probability of less than 0.05 (P<0.05).

**RESULTS AND DISCUSSION**

**Effects on body and organs weight**

The results of this investigation revealed that the mean body weight of the experimental animals was significantly decreased (P<0.05) in all treated groups in both genders after twelve weeks of treatment with lead acetate (table 1). They were reduced to 80%, 77%, and 71% in male while 82%, 78%, and 70% in female when compared to the healthy normal control. The harmful effect of lead acetate on the body weight was significantly increased with the increasing of its dose.

These observations are in accordance with the result of previous studies which reported that lead caused reduction in growth rate in experimental animals when fed lead (Ali et al., 2010; Seddik et al., 2010). It has been observed reduction of body weight in lead induce toxicity in rats (Aseth et al., 1995; Teijon et al., 2006). The body weight gain was decreased after treatment with lead in a dose of 400 mg/kg of the fodder (Szmyezak et al., 1983). The body weight loss might be resulting from the interruption of lead acetate in absorption and metabolism of feed nutrients essential for health (Marija et al., 2004).

At the end of the experimental period, there was a significant increase in some organs weight including liver, kidney, and heart of both male and female under the influence of lead acetate compared to the normal group (table 1). The detected increase in organs weight under the effect of lead might be due to the necrosis and apoptosis which accompanied by the accumulation of lipids in tested organs. Accumulation of lipids
in kidney cells of intoxicated rats after treatment with lead has previously been reported (Hwang and Wang, 2001).

Effects on blood indices

The results in table 2 indicated significant reduction (P<0.05) in the total erythrocyte count (TEC) following exposure of lead acetate in group II, III and IV in comparison with the control group in both sexes. It was also observed marked decrease in the levels of haemoglobin (Hb) and packed cell volume (PCV). MCV, MCH, and MCHC were also significantly reduced in treated mice relative to the healthy ones.

The reduction of TEC and decreased level of other indices are other concordant haematological alteration were observed in the groups where lead acetate was administrated (Falke and Zwennis, 1990; Yagminas et al., 1990) and showed microcystic hypochromic anaemia (Mugahi et al., 2007; Suradkar et al., 2009). Similarly progressive decrease of TEC count, PCV, Hb, and MCV were found following exposure of rats to lead acetate (Helmy et al., 2000; Teijon et al., 2006).

Continuous exposure to lead might adversely affect the heme biosynthesis in the body due to the inhibition of cytoplasmic and mitochondrial enzymes (Atsdr, 1993). The depressing effects of lead acetate on the activity of the major enzymes in heme biosynthesis process might be refer to imperfection of iron metabolism (Chmielnika et al., 1994; Yagminas et al., 1990). The inhibitory effect of lead acetate on conversion of coproporphyrinogen III to protoporphyrin IX resulting in

These haematological changes might be attributed to the TOXIC effect of lead on cell metabolism, interaction with some reactions where calcium is their secondary mediator, and inhibition of some enzymatic activities such as aminolevulinic acid dehydratase which play key role of heme biosynthesis (Klasson, 2001), and other erythrocYTE enzymes e.g GA3PD and G6PD (Calderon-Salinas et al., 1993).
shortening erythrocyte life span and decrease the production of haemoglobin (Klassen, 2001). The reduction of haematological values might be attributed to binding of lead to red blood cells which increase membrane fragility and RBCs destruction (Rous, 2000).

Total leukocyte count (TLC) was also significantly increased in all groups which were administrated lead acetate relative to the control in both genders. It has been reported that lead induced inflammation which lead to increasing in white blood cells (Yagminas et al., 1990) which concur this study. Platelets count revealed considerable increase in intoxicated animals compared to the control. This may be due to thrombocytopenia after lead intoxication (Sudakova et al., 1983) followed by thrombocytosis (Sudakova et al., 1983; Yagminas et al., 1990).

Effects on biochemical parameters

To assess the effect of lead on liver function, the activities of serum AST and ALT were investigated. AST is widely used to evaluate the liver function. ALT is a cytoplasmic enzyme while AST is found in both mitochondria and cytoplasm. The findings of this study indicated significant increase (P<0.05) in the enzymatic activities of ALT and AST in male and female of the intoxicated animals relative to the healthy control ones (table 3). The activities of these enzymes were elevated paralleled with the increase of lead acetate doses. This elevation might be due to increasing of cell membrane permeability or cell membrane damage of hepatocytes under the influence of lead.

These results concur with previous studies reported an elevation in AST and ALT levels after treatment with lead due to acute hepatitis, jaundice, and liver cirrhosis (Mehta et al., 2002; Patil et al., 2007). Lead has hepatotoxic effect resulting in liver cell damage which causes increasing serum levels of AST and ALT (Abdou et al., 2007). It has been observed that lead has toxological effects on rat liver leading to liberation of AST and ALT (Shalan et al., 2005). The high activities of plasma AST and ALT are attached by high liver microsomal membrane fluidity, production of free radicals, and alteration in the liver cells when animals were treated with lead acetate (Ibrahim et al., 2012). Increase in ALT and AST enzymatic activities might be resulting from lead acetate toxicity which causes increased cellular basal metabolic rate, irritability and destructive alteration of liver (Elayat and Bakheet, 2010; Ghorbe et al., 2001). The elevated level of serum bilirubin following exposure to lead may be due to induction of heme oxygenase which play an important role in heme catabolism and can convert heme to bilirubin (Murrey et al., 2006; Seddik et al., 2010).

The results in table 3 also showed that the elevation of lactate dehydrogenase (LDH) was gradually increased with the increasing lead acetate dose in both male and female of all treated animals. Similar findings were achieved in rats dosed with lead acetate (Ibrahim et al., 2012; Seddik et al., 2010) who found gradual stimulation in the activity of LDH in intoxicated rats. The present study also investigated the changes in serum level of alkaline phosphatase (AKP). The activity of AKP was significantly increased (P<0.05) in group II, III, and IV compared to the control group. The effect was elevated paralleled with the increase of lead acetate dose. It has been found an increasing in serum AKP activity might be resulting from liver, kidney, and bone damage leading to releasing of AKP (Kaplan and Reghetti 1970). These results are accorded with other findings (Shalan et al., 2005) in which stimulation of AKP had been noted in rats under the effect of lead. The results of gamma-glutamyle transferase (GGT) showed that the stimulation of serum GGT under the effect of lead acetate was also increased with the increasing lead acetate dose in both sexes. This elevation of serum GGT is an indication of hepatotoxicity and oxidative damage in liver cells (Tatjana et al., 2003).

In the case of kidney function, the concentrations of blood urea nitrogen (BUN) and creatinine were examind to check how well kidney work in intoxicated mice compared to the healthy ones. Significant increase in blood concentration of both BUN and creatinine was detected in male and female (table 3). This elevation might be due to kidney dysfunction and considered as functional evidence of lead induced nephrotoxicity (Patterson, 1965; Zook, 1972). Similar results were found after oral administration of lead in rats (Elayat and Bakheet, 2010; Mugahi et al., 2003), goat (Haneef et al., 1998; Swarup and Dwivedi, 1992) and sheep (Ahmed and Shalaby, 1991).

To conclude, treatment with lead acetate at low doses has harmful effects on experimental animals and induced haematological and biochemical alterations. Therefore, this work advises people to prevent any exposure to this toxic metal to avoid its hazardous impacts on health.
