Key words:
Biomphalaria alexandrina, Thymelaea hirsute, Sinapis arvensis

ABSTRACT

The present study was undertaken to elucidate the efficacy of the crude powder of Thymelaea hirsute, Sinapis arvensis, Callistemon Lanceolatus and Ambrosia martima leaves to control human schistosomiasis through disturbances in fatty acid profile of intermediate host Biomphalaria alexandrina snails. Two concentration of each plants were used (LC10 and LC50) for one week. Snails treated with these plants were then collected and identification of fatty acids composition in snails tissue was carried out using gas liquid chromatography (GLC). The obtained results declared that, alteration in fatty acid profile post treatment of snail with various plant’s powder, fluctuation in reduction percent of long chain and short chain fatty acid contributions either saturated or unsaturated one and decreased in total lipid content, that lead to disturbance in physiological adaption of parasite inside the host which in turn abolish its development. Hence these plant powders can be applied as potential candidate molluscicidal with more potent effect for Callistemon Lanceolatus and Ambrosia martima at high concentration.

INTRODUCTION

Schistosomiasis a dreadful disease caused by parasitic trematode worm in both humans as well as in animals is widespread in the world especially in developing countries, causing high levels of morbidity and mortality in 74 countries in tropical and subtropical areas and most of these people are children. It is considered second only to malaria as a major target disease of the World Health Organization Xiao 2002.

Schistosomes as digenetic trematods have two hosts, a final mammalian hosts and a molluscan intermediate snail hosts. As intermediate hosts Biomphalaria alexandrina (Mollusca; Gastropoda), is widely distributed in Egypt and it plays a major role in the transmission of schistosomes; they are the sites of an intense multiplication of parasites. Thus, snail control strategies are considered a priority for the reduction of schistosomiasis transmission. Elimination of transmission should be the ultimate goal for control strategies. Specific measures such as chemotherapy and snail control have been developed in association with nonspecific measures aimed at the general improvement of sanitary and health conditions and the provision of safe water supplies Brackenbury and Appleton, 1997.

El –Ansary and Qurasby, 1994 stated that the ability of the parasite to develop within snail host is correlated to the snail intrinsic biochemical composition rather than any regulatory immune response. Moreover, Thompson et al. 1991 reported that free living stages of schistosomes are completely dependent on the endogenous reserves acquired from their host in the previous parasitic stage. Cercariae for example, live on their endogenous glycogen and fatty acid stores that they build up while inside the snail host Nabih 1998.

It is well known that fatty acids are among the Snail Conditioned Water (SCW) signals needed by schistosome miracidiae to identify their snail host species Harbel et al., 2000.

In the last few years there have been many investigations concerning lipids and fatty acids in molluscs, Bergmann 1993 summarized the fatty acids of the acetone –soluble lipids of Helix pomatia snail. Venugoplan Enugoplan, 1996 reported some differences in the fatty acid composition of the Oyster crassostrea snails, beside given investigation of fatty acids composition of Ananta arbustorum. Voogt, 1996 declared the fatty acids composition of Sucinla putris snails. Moreover, Ackman and Hooper, 2000 determined the distribution of saturated fatty acids in the lipids of three species of marine molluscs.

Fatty acids is very important, since anoxia is generally accompanied by a marked hydrolysis of membrane phospholipids. Free fatty acids (FFA) and in particular poly-unsaturated fatty acids (PUFA) play a vital role in the biochemical adaptation to hypoxia prevailing during host – parasite complex Marcel 1994.

El –Ansary et al. 2001 could induce in vivo attenuation of schistosome cercariae using sublethal concentrations of selected plant molluscicides which include, Thymelaea hirsute(Shaggy Sparrow-Wort, Spur flax), Sinapis arvensis (Wild mustard or charlock), Callistemon Lanceolatus (Lemon Bottlebrush or Crimson Bottlebrush) and Ambrosia martima.
(Sea Ragwood). Although, the reduced number of attenuated cercariae released from the treated snails showed normal skin penetration rate while, worm burden and egg count in the liver and intestine of mice infected with plant molluscsicides – attenuated cercariae were remarkably lower compared to those infected with normal cercariae. Number and size of granulomatous reactions showed significant reduction in attenuated cercariae –infected mice.

The use of molluscsicides has always been considered to be a major supportive procedure in integrated schistosomiasis control (Brackenbury and Appleton, 1997) Synthetic molluscsicides have met with limited success in controlling the host snails, such as Biomphalaria alexandrina Biomphalaria pfeifferi and Biomphalaria truncatula, for several reasons one of which is their high cost which places them beyond the economic reach of developing countries. As, an alternative attention has focused on plants with intrinsic molluscicidal properties. The purpose of utilizing plant products is to provide infected rural communities with a cost-effective, locally available and biodegradable molluscicide (Brackenbury and Appleton, 1997). Ambrosia maritima (family, Asteraceae) is distributed in Senegal and is known to be molluscicidal with low toxicity to non-target organisms (Belot 1993). The active compounds in the plant are thought to be sesquiterpenes and diterpenes (De Leo,2010). All Ambrosia species are characterized by a high content of sesquiterpene lactones, which account for cytotoxicity, molluscicidal, antibacterial, antifungal and other pharmacological activities Parkhomenko, 2006. While, Durkeet and Harborne , 1973. Appelqvist et al. 1981. Onyilagha et al. 2003 and Agerbirk et al. 2008 reported that, the molluscicidal and biological activities of Sinapis arvensis (tribe Brassiceae, Brassicaceae), was related to flavonol aglycons, composition of steroids and 4-hydroxyphenylacetonitrile degrading enzyme activity. On the other hand, Thymelaea hirsute (Thymelaeaceae) was shown to have alcohols and phenols particularly benzene propanol, benzyl alcohol, nonanol, hexanol and 4-methoxyphenol Odeh 2007. Varma and Parthasarathy 1975 reported that, the molluscicidal and antifungal activities of Callistemon Lanceolatus (myrtaceae L.) related to triterpenoids.

These information initiated our interest to compare the fatty acid profile of control and molluscsicides –treated snail in a trial to find out if different fatty acids are contributed to the previously reported remarkable reduction in snail compatibility to schistosome parasite El-Ansary 2003 which could easily correlated to the attenuation of cercariae released from molluscicide–treated snails.

**MATERIALS AND METHODS**

**Snails**

Stock culture of Biomphalaria Alexandrina snails were used in the present study. They were collected from Abu Rawash, Giza Governorate and were kept under standard laboratory conditions in the glass aerated aquaria, filled with dechlorinated water at 25 ± 2°C, fed on fresh lettuce leaves ad lib and left for 45 days to ensure that they were free from infection. They were about 3 months old and their individual weight between 500 to 700 mg. Thymelaea hirsute, Sinapis arvensis, Callistemon Lanceolatus and Ambrosia maritima are

wild herbs. These plants were collected Egyptian country, dried and used as powder. The chemicals used were of analytical quality and purchased from Merck, Germany.

**Treatment**

B. alexandrina snails with a shell diameter of 10-15 mm were exposed to LC$_{10}$ and LC$_{25}$ values (LC$_{10}$ of Thymelaea hirsute, Sinapis arvensis, Callistemon lanceolatus and Ambrosia maritima represented by the concentrations of 6, 3, 5 and 9 ppm of the plant powder while LC$_{25}$ of the same mentioned plants represented by the concentrations of 15, 7.5, 12.5 and 22.5 ppm respectively ) of Thymelaea hirsute, Sinapis arvensis, Callistemon lanceolatus and Ambrosia maritima plants as they were obtained from the toxicity lines statistically calculated according to the method of Finney 1952, Soliman and El Ansary, 2007. LC$_{10}$ and LC$_{25}$ values were dissolved in dechlorinated water which has the snails for one week El-Ansary, 2001. Whole snail bodies weighing 500-700 mg (wet weight) were collected from pools of 5 to 7 Thymelaea hirsute, Sinapis arvensis, Callistemon lanceolatus and Ambrosia maritima treated - snails. A total of three pools of each plants treated snails were analyzed in this study as recommended before by Higgs et al. 1990.

**Isolation of native lipids**

Lipids were extracted from snails bodies with 10-14ml of chloroform –methanol (2:1 ), the extracts were filtered through a plug of glass wool contained in a pasture pipette and non- lipid contaminants were removed by extraction with 8-10 ml of Folch wash (0.88% aqueous KCl solution). The lipid –containing lower phase separated and evaporated just to dryness under a stream of nitrogen at room temperature. The total lipid sample were dissolved in approximately 30 ml of methanol and 0.5-1.0 ml of concentrated sulfuric acid was added. The mixture was refluxed for 1 hr, the formed fatty acid methyl esters was extracted with 30-40 ml of petroleum ether (40-60 °C), and the extract dried over anhydrous sodium sulfate. The fatty acid methyl esters were concentrated on a Rotor evaporator at 40 °C and the volume reduced to 1 ml. One microlitre of each concentrated test solution was injected into gas chromatography (GLC) using a 10 ul syringe Fried,1991. The analysis GLC was performed in the National Research Center (Unit of central services) Dokki, Cairo, Egypt.

**Lipid analysis by gas liquid chromatography (GLC)**

**Determination of saturated and unsaturated fatty acids in total lipids**

The GLC analysis of fatty acid methyl esters was carried out by using a Hewlett –Packard Model 5890-A gas chromatograph fitted with a polar (Supelcowax TM$_{10}$) fused silica capillary column ( 30m x 0.32mm ) (Supelco, Inc.,Bellefonte, PA), flame ionization detector, and data processor. The helium carrier gas used at a pressure of 12 psig, and the injection port, column, and detector temperature were maintained at 220, 210 and 220 °C, respectively. GLC peaks were identified by comparison with the retention times of fatty acid methyl ester standards (obtained from Sigma Chemical Co., USA) and cod liver oil fatty acid methyl esters. Identification of peaks by GLC representing lipids with different numbers of double bonds was confirmed by
comparison of the Rf (Rf is the distance of compound / the distance of solvent) values of standard and samples separated by argentation TLC Morris, 1962. Silica gel layers containing 9% (w/w) silver nitrate were developed with diethyl ether–hexane (1:9) mobile phase, and lipid zones were detected by spraying the plate with 2,7-dichlorofluorescein and inspection under 254 and 366 nm UV light.

Quantitative results were determined by area normalization, in which the percentage of each component is calculated from the percent of total area which is represents.

Biochemical estimation of total lipid

The level of total lipid of negative and treated snails was estimated according to the method of Zollner and Kirsch Zollner, 1962.

Statistical analysis

Analysis of data was carried out by one way analysis of variance with the Costat Computer Program, where the significance level at p≤0.0001.

RESULTS

Results presented in the table 1 and Fig 1 show the area percentage of fatty acid compositions which is the major components of the total lipid isolated from tissue homogenates of B. alexandrina intermediate host of Schistosoma mansoni species as a result of different plant treatments.

It can easily be noticed that free fatty acid (F.F.A) composition varies between different treatments. About 15 different fatty acids were consistently detected in B.alexandrina species. In general the major component of the FFA fraction were C15:0, C16:0, C16:1, C17:0, C16:1, C16:2, C16:3 and C20:0.

It was shown that, treatment of snails with LC10 and LC25 concentrations of Thymealaea hisurate, Sinapis arvensis, Callistemone lanceolatus and Ambrosia maritima produced remarkable alterations in the percentage of fatty acids contributions. These changes are summarized as follows:

1. control snails, have ten saturated fatty acids: C8, C0, C10-C12, C14, C15-C16, C17, C18 and C20 and five unsaturated fatty acids: C14:1, C16:1, C18:1, C18:2 and C18:3.

2. Treated snails with Thymealaea hisurate (LC10) have nine saturated fatty acids: C8, C9, C10, C12, C14, C15, C17, C18, C20 while C16 is not detected as a result of plant treatment. On the other hand, unsaturated profile of fatty acid shows three contributions of C18:1, C18:2 and C18:3.

It can be demonstrated that, significant increase in capric (C10), lauric (C12), myristic (C14), stearic (C18) saturated fatty acid contributions as compared to normal control. While significant decrease in saturated caprylic (C8), pelargonic (C9), pentadecylic (C15), unsaturated linoleic and lenolenic fatty acids (C18:2 and C18:3) as compared to normal control.

3. Snails treated with Thymealaea hisurate (LC25), have the same previous mentioned fatty acids with remarkable drastic effect, where capric fatty acid (C10) was not detected and arachidonic acid (C20) fatty acid contribution shows significant reduction as compared to normal control.

4. Treated snail with Sinapis arvensis (LC10) have nine detected mono-saturated fatty acid C8, C9, C10, C12, C14, C15, C17, C18 and C20 with significant increase in concentration percent of C10, C12, C14, C17 and C18 while, significant decrease in the others as compared to normal control. Considering, polyunsaturated fatty acids, C18:1, C18:2 and C18:3, significant decrease was recorded as compared to control. It is obviously that, one saturated (palmitic C16) and two unsaturated fatty acids (C14:1 and C16:1) were disappeared or not detected. In addition, upon treatment snails with LC25 of Sinapis arvensis the same pattern of both monosaturated and polyunsaturated fatty acids was recorded with severe drastic effect (dose dependent concentration relationship).

5. Treated snail with LC10 of Callistemone lanceolatus demonstrated nine saturated fatty acids C8, C9, C10, C12, C14, C15, C17, C18 and C20. Among them C8, C9, C15 and C20 recorded significant reduction, while significant increase was detected in others determined fatty acids (C14, C17 and C18). With respect to unsaturated fatty acids, three unsaturated contributions were observed, C18:1, C18:2, C18:3 and exhibited significant decrease upon treatment of snail with LC10 of Callistemone lanceolatus. LC25 have the same fatty acids pattern with more percentages of reduction was recorded (dose dependent) and disappearance of C8 and C10.

6. Furthermore, snails treated with LC10 of Ambrosia maritima showed also the same fatty acid profile of nine saturated fatty acids with fluctuated significant percent, where C8, C9, C15 and C20 exhibited significant reduction, while C10 shows insignificant change and C12, C14, C17, C18 demonstrated significant elevation respectively as compared to the normal control group. On the other hand, the three detected polyunsaturated fatty acids C18:1 and C18:3 showed significant reduction, while C18:2 shows insignificant change as compared to the normal control. Concerning, LC25 of Ambrosia maritima, it demonstrated identical both saturated and unsaturated profile of fatty acids with remarkable effect (dose dependent) in addition to, disappearance of C8, C9 and C20 fatty acids contributions. Hence fatty acids contributions were affected by different plants in a dose – dependant fashion.

The current data indicate that, the mean chain lengths and unsaturation index are significantly reduced in B-alexandrina snail post various plant treatments and these low levels are more obvious upon using high concentration of the selected plants.

The present results declared also, significant reduction in total lipid upon treatment B. alexandrina snail with different plants.

Values represents mean ± S.D of three independent experiments and is expressed as moles percentages.

Total lipid is expressed in mg/dl.

Mean chain length is defined as \( \sum f_i c_i \), where \( f_i \) is the molar fraction and \( c_i \) is the number of carbon atoms of fatty acids.

USI: Unsaturation index and is defined as \( \sum f_i c_i^2 \) or \( m_i + n_i \) where \( m_i \) is the molar percentage and \( n_i \) is the number of carbon–carbon double bonds of fatty acids.

Statistical analysis is carried out using one way analysis of variance with Costat Computer Program, where unshared letters is significance at \( p \leq 0.001 \).

**DISCUSSION**

Little information is available on tissue free fatty acids (FFA) patterns of freshwater B. alexandrina snails. The present study demonstrated that FFA composition of B. alexandrina treated snails vary between the selected plant treatments.

Fatty acid profile of control B. alexandrina snails reported in the present study is more or less similar to that reported in the Digestive Gland –Gonad complex (DGG) of Biomphalaria glabrata [25]. Quantitative analysis of the present study revealed the presence of, 15 different fatty acid contributions upon treatment B. alexandrina with different molluscicidal plants. In general, the major components of the FFA fraction were C_{15}, C_{16}, C_{16}, C_{17}, C_{18}, C_{18}, C_{18}, C_{20}, C_{18}.

The present results are concerned with marked depletion in the level of long chain fatty acids (C_{16}, C_{18}, C_{18}, C_{20} in...
Thus the reduction in the percentage contribution of these fatty acids may be considered as a prerequisite for biochemical adaptation. Being in an environment or medium of linoleic acid activity of intermediate host Fried et al. 1993. In addition, C18:2 and C18:3 were stimulated. Depletion of some long chain and short chain fatty acids may be explained on the basis that reduction in rates of glucose metabolism in the snails was balanced through the stimulation of triglyceride hydrolysis and fatty acid oxidation. The snails can tolerate the lower concentration (LC0). The ability of the snails to tolerate the reduction in rates of glucose metabolism which induced by plant-treatments was decreased by increasing the concentrations of the plants, i.e. at LC25 less lower chain fatty acids were detected and lower concentration for that detected Ahmed SA, El –Ansary, 1994. Altered fatty acids spectra recorded in the present study may lead to abnormal signals which in turn could disturb the snail –finding mechanisms by schistosome miracidiae Korner and Hass, 1998.

Mahmoud et al. 1999 supporting the present results by declared that Ambrosia maritime L. (Asteraceae) showed molluscidal and ovicidal activity and hence it used for control of bilharziasis and was proved to have lethal effect on snail miracidiae and cercaria. The adverse effect of Ambrosia maritime was found related to its active compounds sesquiterpenes and diterpenes De Leo and Saltos 2010. However, Soliman and El –Ansary, 2007 found that, Ambrosia maritime showed only slight alteration in amino acid levels compared to hirsute, Sinapis arvensis, Callistemon Lanceolatus. The present data declared that, the four selected plants are effective by different degree (Fig.1), and these may explained on the basis that, these effective plants could have immunostimulatory effect through induced lysine amino acids which is considered as a critical importance in inducing parasite killing by hemocytes of molluscicides –treated snails Soliman and El –Ansary, 2007. The significant alterations in fatty acid pattern in the present study could be used to explain the decrease in snail compatibility previously reported by El-Ansary et al. (12,32, 33), as reduction in the mean total number of cercariae shed each B. alexandrina snails treated with the same molluscicides. These could be easily correlated to the reduction or indictable levels of the major component of fatty acids and hence fatty acid cycle and all biochemical process.

Intermediate host B. alexandrina snail was shown to have high contribution of poly-unsaturated fatty acids (PAFA) C18:1, C18:2, C18:3 and C20:0), while enhancement of C17:0 and C16:0 in either saturated or unsaturated of B. alexandrina snail post various plant treatments. Moreover, the short chain fatty acids C8:0 and C6:0 observed in the tissue homogenates of the various plants –treated snails were detected in traces values, although C10:0 C12:0 and C14:0 were stimulated. \( C_{18:1} \) availability is considered as an aspect of biochemical adaptation. Being in an environment or medium rich with linolic acid may be considered as a prerequisite for the schistosoma parasite to be transformed into cercariae more efficient for penetration and development in the final host. Thus the reduction in the percentage contribution of these fatty acid inhibited the transformation of schistosoma parasite into cercariae Zanotti 1995. However, Harra et al. 1993 proved that oleate \( (C_{18:1}) \) and linoleate\( (C_{18:2}) \) fatty acids induced strongly tail removal in S. mansoni cercariae and calcium enhanced the cercarial tail –loss rate. These findings suggested that the decreased percent of these fatty acids contributions caused inhibition of calcium influx into cercariae, resulting in preventing tail loss and hence abolish the transformation process of schistosoma parasite into schistosomula. On the other hand, caprylic, capric and margaric were not reported to have any biochemical significance Zanotti et al 1995.

Randall et al. 1993 and Marcel et al. 1994 suggested that, polyunsaturated fatty acids and prostaglandins play a role in the physiological response to hypoxia. Reduced level of these contributions \( (C_{18:1}, C_{18:2}, C_{18:3}) \) and lower unsaturation index\( (USI) \) in snail - treated plants may be an important to un-adapt condition that prevent aerobic- anaerobic transition induced by the schistosoma parasite.

It is well known that, fatty acid pattern of the molluscan hosts is of great importance for developing parasite, in this concern, Fukushima et al. 1993 reported that arachidonic acid \( (C_{20:0}) \) metabolized to prostaglandin \( E_2 \) (PGE\( _2 \)) by intermediate host B.alexandrina snail. PGE\( _2 \) is known to suppress the functions of mononuclear cells and immune system of the intermediate host to enable the development of parasite inside the host. Low percentage contribution of arachidonic acid post different treatment of plants leads to decrease in the level of PGE\( _2 \) and enhancement in immune system of the host that in turn overcome parasite development.

In addition, the detected low level of saturated arachidonic acid in B-alexandrina snails post treatments with various plants indicating disturbance of many enzymes including those involved in fatty acid oxidation (acetyl CoA carboxylase, fatty acid synthase and citrate ligase Jamp, 2002 TCA cycle functioning (pyruvate dehydrogenase, citrate synthase Pastural et al, 2009 a-ketoglutarate dehydrogenase Lai et al 1993, glutamate dehydrogenase Pastural et al, 2009 and oxidative phosphorylation Ventura, 1996. Accumulation of intermediates of fatty acid oxidation may be considered as toxic mechanisms. In addition, lactate is accumulated and glycogen, lipid are depleted (Crabtree effect) confirming inhibition of aerobic respiration and stimulation of anaerobic glycolysis.

The current results demonstrated significant reduction in the total lipid of B. alexandrina snails post various plant treatments. In a parallel results Fried et al. 1993 reported that the fatty acid difference in B. alexandrina snail post various molluscicidal treatments probably reflect differences in their available lipid pools and their metabolic activity. The reduction in total lipid may confirm the disturbance in fatty acid metabolism, oxidative phosphorylation, transformation process of lipids into glucose and aerobic-anaerobic transition induced by developing parasite (Crabtree effect) which is a vital for intermediate host to withstand under stressed condition Telien, 1997.

El-Ansary et al. 2003 showed that sublethal concentrations\( (LC_{10} \) and \( LC_{25} \)) of the plant molluscicides used in the present study were effective in reducing fecundity of the treated snails, normal cercariae penetration rate in spite of
their attenuation and decrease of their pathogenicity to the mammalian hosts. This could find support in the present study, since the changes in the major fatty acid fractions are correlated with disturbances in the major biochemical pathways previously reported Tielen et al., 1997.

In conclusion, treatment of Biomphalaria alexandrina snails with sublethal concentrations of Thymelaea hirsute, Sinapis arvensis, Callistemon Lanceolatus and Ambrosia maritima can be applied safely for non-target organism and were effective in altering the fatty acids profile of this snail species which could be contributed to disturbance in biochemical mechanisms, abolish the developmental process of schistosome parasite inside the host, impairment of snail egg laying capacity and snail—schistosoma miracidia finding mechanisms. Hence these plants are shown to have potential candidate molluscicidal with more potent effect for Callistemon Lanceolatus and Ambrosia maritima at high concentration.
