ABSTRACT

Three fungal strains that produced ligninolytic enzymes were isolated from palm oil plantation soils. Isolate MIRT 1 was identified as Aspergillus niger isolate MIRT 2 was identified Aspergillus flavus, and isolate MIRT 3 was identified as Trichoderma viridae. These strains utilized lignin as the sole source of carbon and produced the main ligninolytic enzymes; lignin peroxidase, manganese peroxidase, and laccase. Based on the results obtained in this study, the isolate Aspergillus niger MIRT 1 was chosen as the best of the ligninolytic fungal strains, as it achieved maximum manganese peroxidase production of 2221.4 U/L on the third day under the optimum conditions of pH 8 and 30 °C. Strain Aspergillus niger MIRT1 also produced the highest lignin peroxidase, at 204.45 U/L, on the fifth day of fermentation under the optimum conditions of pH 8 and 30 °C. Strain Aspergillus flavus MIRT2 showed the highest laccase enzyme production of the three selected fungal strains in the present study. Although the production of manganese peroxidase and lignin peroxidase by strain Aspergillus flavus MIRT2 was lower than Aspergillus niger MIRT1, Aspergillus flavus MIRT2, Trichoderma viridae MIRT3 showed the highest laccase enzyme at 11.12 U/L on the fifth day under the optimum conditions of pH 7.5 and 35 °C. The Trichoderma viridae strain has been considered a novel ligninolytic fungal isolate from palm oil plantation soil. Phanerochaete chrysosporium Standard culture showed bet results compared to the isolates though the isolates compete with that. For any environment if there is a mixture of these fungi then there will be great degradation of lignocellulose, which could be used commercially and/or industrially.

INTRODUCTION

Lignocelluloses biodegradation

Lignocellulose is a complex substrate and its biodegradation is not dependent on environmental conditions alone, but also the degradative capacity of the microbial population (Waldrop et al., 2000). The composition of the microbial community charged with lignocellulose biodegradation determines the rate and extent thereof. The efficient hydrolysis of cellulose requires the concerted action of at least three enzymes: (1) endo-glucanases to randomly cleave intermonomer bonds; (2) exoglucanases to remove mono- and dimers from the end of the glucose chain; and (3) β-glucosidase to hydrolyze glucose dimmers (Deobald & Crawford, 1997; Tomme et al., 1995). The concerted actions of these enzymes are required for complete hydrolysis and utilization of cellulose. The rate-limiting step is the ability of endo-glucanases to reach amorphous regions within the crystalline matrix and create new chain ends, which exocellulohydrolases can attack.

Although similar types of enzymes are required for hemicellulose hydrolysis, more enzymes are required for its complete degradation because of its greater complexity compared to cellulose. Of these, xylanase is the best studied enzyme (Kuhad et al., 1997). Although the model described in Figure 1 was developed from data obtained from Trichoderma koningii and Phanerochaete chrysosporium, it does well to describe the general aspects of enzymatic hydrolysis of cellulose (Tomme et al., 1995). However, a fundamental difference exists in the mechanism of cellulose hydrolysis between aerobic and anaerobic fungi and bacteria (Leschine, 1995; Tomme et al., 1995).

Lignin degradation by white-rot fungi is an oxidative process and phenol oxidases are the key enzymes (Kuhad et al., 1997; Leonowicz et al., 1999). Bacterial and fungal feruloyl and p-coumaroyl esterases are relatively novel enzymes capable of releasing feruloyl and p-coumaroyl and play an important role in biodegradation of recalcitrant cell walls in grasses (Kuhad et al., 1997). These enzymes act synergistically with xylanases to disrupt the hemicellulose-lignin association, without mineralization of the lignin (Borneman et al., 1990).

MATERIALS AND METHODS

Site And Sample Collection

Soil sample were collected from three different sampling sites in around Arcot, from the area where an old dead wood identifies. The samples were collected from decayed wood...
surroundings. The soil samples were collected from the surface to a depth of about 0 to 10 cm using sterile spatulas and transported to the laboratory and stored at -20°C.

### Soil Characteristics

Soil characteristics were determined using standard methods (APHA, 1985). For each sampling site, three soil samples were combined and mixed together to construct a composite sample. Acid detergent fiber (ADF), neutral detergent fiber (NDF), and acid detergent lignin (ADL) methods were used to determine the cellulose, hemicellulose, and lignin compositions respectively, of the samples (Goering and Van Soest, 1970).

### Phanerochaete Chrysosporium Standard Culture

Spore inoculum was prepared from 7-8 day old petri plates of PDA-grown ATCC 24725 obtained from MTCC, Chandigarh (grown at 39°C) harvested with 0.85% sterile saline with the aid of a glass hockey stick. Spore counts were determined by hemocytometer.

### Fungal Isolation And Screening

1. For isolation of the soil fungi, 1g of soil sample was added to 100 ml of sterile 0.9% NaCl. The solution was stirred vigorously and then allowed to settle.
2. One milliliter of the liquid was mixture was serially diluted until a dilution of 10⁶.

### Submerged Fermentation

a) The isolated fungal strains were named as TRY1, TRY2 and TRY3.

b) One loopful of each selected fungal strain was inoculated into 10 mL of PDA broth medium at an initial concentration of 10⁵ cells/mL.

c) Samples were incubated at 30 °C with shaking at 120 rpm for 10 h to obtain a final OD value of 1.0 at 600nm.

d) Then, the inoculums were transferred to 250 mL Erlenmeyer flask containing 90 mL of PDA medium and 0.9 g/L of lignocellulose loaded soil.

### Observation of Colony Shape, Texture and Pigmentation

The purity of each strain was ensured by microscopic observation of colony shape, texture and pigmentation.
e) The cultures were incubated at 120 rpm and at 30 °C for 7 days.
f) The initial pH was set at 7.6. Sampling was performed at every 24 h to observe daily fungal growth (OD). *Escherichia coli* strain was used as a negative control.

**Preparation Of Crude Enzymes**

Samples were collected at every 24 h and their turbidity was measured by reading the OD at 600nm. The supernatants and pellets were separated by centrifugation at 8,000 rpm for 10 minutes. The supernatants were collected and were used to measure extracellular ligninolytic enzyme activity.

**Lignin Peroxidase Enzyme Assay**

The lignin peroxidase (LiP) activity was assayed via the oxidation of veratryl alcohol to veratraldehyde at 310 nm (Tien and Kirk, 1988).

**Manganese Peroxidase Enzyme Assay**

Manganese peroxidase (MnP) activity was measured via the oxidation of guaiacol to a colored product using the UV-Vis spectrophotometer at 465 nm (Li et al., 2008).

**Laccase Enzyme Assay**

Laccase activity was determined by oxidation of 2,2’-azinobis-(3-ethylbenzethia- zoline-6-sulphonate) (ABTS) using the method of Wolfenden and Willson (1982).

**Effect of pH concentration**

The effect of initial pH was evaluated via submerged fermentation of the selected isolates in PDA broth medium with the addition of 0.5 g/L lignocellulose loaded soil at 5 different initial pHs.

The optimum initial pH for enzyme production was determined by incubating triplicate samples of the selected isolates at pH 7.0, 7.5, 8.0, 8.5, and 9.0, using 1 M HCl or 1 M NaOH to adjust the pH. The experiments were all conducted in an incubator shaker set at 120 rpm and 30°C for 7 days. Samples were collected at every 24 hours.

**Effect of temperature variation**

The optimum temperature for ligninolytic enzyme production was investigated by incubating triplicate samples of the selected isolates in PDA broth medium with the addition of 0.5 g/L lignocellulose loaded soil at temperatures of 30, 35, 40, 45, and 50 °C. The flasks were incubated at 120 rpm on a rotary shaker for 7 days, and samples were collected at every 24 hours.

**RESULTS & DISCUSSION**

Three newly isolated fungal strains that produced ligninolytic enzymes were isolated from palm oil plantation soils. Isolate MIRT 1 was identified as *Aspergillus niger* isolate MIRT 2 was identified as *Aspergillus flavus*, and isolate MIRT 3 was identified as *Trichoderma viridae*. These strains utilized lignin as the sole source of carbon and produced the main ligninolytic enzymes: lignin peroxidase, manganese peroxidase, and laccase. Based on the results obtained in this study, the isolate *Aspergillus niger* MIRT 1 was chosen as the best of the ligninolytic fungal strains, as it achieved maximum manganese peroxidase production of 2221.4 U/L on the third day under the optimum conditions of pH 8 and 30 °C. Strain *Aspergillus niger* MIRT1 also produced the highest lignin peroxidase, at 204.45 U/L, on the fifth day of fermentation under the optimum conditions of pH 8 and 30 °C.
previous reports by Kuwahara et al., (1984) and Zhu et al., (2013). It was stated in a previous report that some of the ligninolytic fungi were also isolated from soil are thermophilic strains (Oliveira et al., 2009). Based on the results, at 35 °C, 204.45% of the LiP activity was retained, while further increases in the temperature have resulted in drastic decreases in activity. This indicated that higher temperatures resulted in gradual inactivation of the LiP (Bibi and Bhatti, 2012). For manganese peroxidase, Aspergillus niger MIRT 1 produced the highest enzyme activity at a temperature of 30 °C. For laccase, the fungal Aspergillus flavus MIRT 2 produced a maximum activity of 11.12 U/L on day 5, even though at 35 °C, the LiP and MnP enzyme activities were highest for Trichoderma viridae MIRT 3. The laccase enzyme activity was lower at a temperature of 30 °C. In previous studies, most of the isolated ligninolytic fungal could only produce two main ligninolytic enzymes, especially a combination of MnP and Lac enzyme production (Shi et al., 2013; Chen et al., 2012; Oliveira et al., 2009). Meanwhile, in this study, all three isolated strains produced all three main ligninolytic enzymes: LiP, MnP, and Lac. Regardless of the other findings, only MnP and LiP showed comparable enzyme activity with previous studies, while the Lac enzyme activity results showed the lowest activity. The maximum Lac obtained in this work was from Aspergillus flavus MIRT 2 which was 11.12 U/L, while Phanerochaete chrysosporium sp. B-9 is at 1250 U/L based on Chen et al., (2012). Shi et al., (2013) reported that Cupriavidus basilensis B-8 can produce Lac up to 815.6 U/L. Based on the present work, Aspergillus niger MIRT 1 can produce a maximum MnP at 2221.4 U/L, which is higher than for Cupriavidus basilensis B-8 at 1685.3 U/L (Shi et al., 2013). However, the MnP activity from Phanerochaete chrysosporium is still the highest at 2903.2U/L, as reported in Chen et al., (2012). Based on these results, it can be concluded that the present isolated fungi can produce ligninolytic enzymes at comparable activity when compared with previous studies.

The results of the present study confirmed that three newly isolated fungal strains from palm oil plantation soils can grow on kraft lignin as a sole carbon source and can produce three main types of ligninolytic enzymes in vitro and in vivo. Further studies are required to measure lignin degradation of lignocellulosic biomass by these fungal strains. Moreover, future studies may determine other optimum conditions in addition to pH and temperature, such as nutrients, dissolved oxygen level, and fungal concentrations to maximize the production of ligninolytic enzymes by pure or mixed cultures of these newly isolated strains.

ACKNOWLEDGEMENT

The authors express their sincere gratitude to the staff members of Microlabs, Institute of Research and Technology, Arcot, Tamilnadu, for providing working environment.
